

Impact of Catastrophic Floods on Gendered Labor Supply: Evidence from India

Abstract

In less developed economies, frequent climate events continue to threaten both gender equality and stability of local labor markets. This study examines how flood shocks affect the gender gap in paid labor outcomes. Using cross-country panel data, I first show the non-linear relationship between flood shocks and gender gap in labor force participation. Using the catastrophic 2018 floods in the Indian coastal state, Kerala, this paper employs a difference-in-difference design using a population weighted measure of flood exposure to define treatment districts. Key findings indicate that the flood shock significantly reduces paid labor hours of both men and women, with a disproportionately larger impact on women. These effects are especially pronounced in rural areas. Casual labor is the most vulnerable to the flood while self-employment emerges as a key coping mechanism, particularly among men. Moreover, marital status and dependency burden further shape the extent to which the flood affects paid labor outcomes differently between men and women.

1 Introduction

Globally, floods are the most prevalent weather related disasters. 23% of the world’s population is exposed to a catastrophic or 1-in-100 year flooding (Rentschler et al., 2022)¹. Less developed and developing countries are home to 1.61 billion flood exposed people (Rentschler et al., 2022). Nearly one in five of these people lives in India (Rentschler et al., 2022). As global average temperature is set to exceed 1.5 °C in the next two decades, extreme weather events such as floods, cyclones, and droughts are likely to become more frequent and intense (IPCC, 2021). By 2030, 147 million lives will be hit by riverine and coastal floods (Meyer, 2020).

In low- and middle-income countries, gender inequality is a major challenge and extreme weather events further worsen it. Existing studies have shown that floods increase discriminatory behavior against women such as early marriages (Dietrich et al., 2022; Khanna & Kochhar, 2023), intimate partner violence (Abiona and Koppensteiner, 2018; Guo et al., 2025), food insecurity (Hadley et al., 2023; Asfaw and Maggio, 2017), and migration (Sheldon and Zhan, 2022; Wang et al., 2025). However, less attention has been paid to how catastrophic floods impact men’s and women’s paid labor outcomes.

Evidence is mixed when it comes to how floods reshape gendered paid labor responses. On one hand, floods can increase women’s labor supply to smooth financial hardships. After the 2014 Bangladesh flood, previously non-employed women increased their paid labor participation (Canessa and Giannelli, 2021). Similarly, women spent more time than men on income-generating activities after facing consecutive floods in 2014 and 2017 in Bangladesh (Vitelloszi and Giannelli, 2024). On the other hand, floods can also deter women from working outside by reducing sectoral demand, inflexible migration and increasing unpaid household responsibilities. In India, for instance, flood-related damages reduced women’s employment more than men in the agricultural sector (Chowdhury et al., 2022). This gender gap is often worsened by rising unpaid care work and domestic work after floods (Enarson, 2000; Erman et al., 2019). While men are more likely to migrate to seek non-farm income opportunities after floods, women mostly stay behind to take care of household members and face reduced paid labor (World Bank, 2022).

This study examines whether and to what extent extreme climate shocks impact gender disparities in the paid labor market, specifically, men’s and women’s participation in paid labor. Specifically, this study seeks to assess the impact of a catastrophic flood that occurred in Kerala, an Indian coastal state, in 2018 on gender differences in paid employment outcomes. Key findings show that the effects of 2018 Kerala flood were more pronounced on the intensive margin than on the extensive margin. Women’s weekly paid labor declined by 1.42 hours after the flood, which represents nearly a 23.5% drop relative to pre-flood levels, while men’s working hours declined by 1.16 hours

¹Note that 1-in-100 year flood refers to an extreme flood event which has 1% probability of occurrence in a year.

per week but not significantly. The latter corresponds to 7.3% decline compared to the pre-flood levels. Thus, women were more adversely affected in the post-flood labor market. While the effect of the flood was statistically insignificant on employment participation, it is noteworthy that women’s employment participation declined by 1.6 percentage points (pp) but men’s employment participation increased by 1.7 pp. This implies that those who remained employed reduced their working hours, particularly men. When I focus on districts that are less affected by the flood, I find that men’s employment participation recovered by 3.2 pp and their paid labor hours declined only marginally. However, women’s weekly paid labor declined by 1.55 hours in less affected districts after the flood. This implies that women’s employment is more vulnerable after floods irrespective of whether they are in more affected or less affected districts. The results remain robust under all alternative definitions of treatment groups—(a) districts closer to mismanaged dams and (b) districts affected by flood-induced landslides.

Moreover, the results show interesting heterogeneous effects shaped by location of dwelling (rural/urban), sector of employment, and gender norms. Urban labor markets appeared relatively more resilient than rural labor markets for both men and women. Casual labor is found to be most vulnerable to floods and self-employment emerged as a fallback position. The latter implies a shift toward more home-based work after the flood. Gender norms, reflected in marital status and dependency burden, explain these divergent outcomes. Married women were more likely to reduce their paid labor supply compared to unmarried women. Similarly, women in households with a higher share of dependent family members were more likely to cut back on paid work, while men increased their labor supply in response. By contrast, women were more likely to increase their paid labor hours in low-dependency households, while men’s labor supply was relatively muted. These findings are consistent with social expectations around gender, especially in less developed countries.

My findings contribute to the emerging studies that examine the relationship between climate extremes and labor dynamics in developing countries. Afridi et al. (2022) found that droughts reduced women’s agricultural workdays relative to men’s. Maitra and Tagat (2024) reported that negative rainfall shocks increased men’s participation in regular wage work by nearly 0.6 days per week while having an insignificant effect on women’s involvement in paid work. Conversely, studies on flooding present differing results: the probability of non-employed women entering employment increased by 13 percentage points in the aftermath of the 2014 floods in Bangladesh (Canessa & Giannelli, 2021). The 2017 Bangladesh floods increased women’s participation in market activities, while men took on more domestic responsibilities (Vitelloszi & Giannelli, 2024). However, it is important to note that the term “market activities” is not restricted to participation in jobs where an individual directly gets paid but also includes unpaid contributions to family establishments (Vitelloszi & Giannelli, 2024). In low- and middle-income countries, most women engage in unpaid work within the family business which, even though categorized as market activities, does not generate any income in the hands of the laborer. According to the ILO definition, such individuals

are “contributing family workers” who cannot be considered at similar levels as the self-employed in family enterprises because their degree of commitment to the operation of the establishment is not comparable to that of the head of the establishment.

My research contributes to this recent strand of literature in two possible ways.

First, most publicly available labor force surveys and household survey data in developing countries provide district-level data without georeferenced information. This poses challenges for impact assessment by using a more granular level for treatment. To address this, I demonstrate a method to construct district-level population exposure estimates using satellite-based flood data from Google Earth Engine (GEE). By combining the proportion of flooded area and population at the sub-district level and averaging this for each district, I produce a weighted exposure measure. This approach offers a method to define treatment at the district level when georeferenced survey data is unavailable.

Second, there exists a lack of empirical studies on the effects of floods on labor market outcomes in South Asia, particularly in India. Existing studies have focused on droughts or rainfall variability when examining the nexus between climate shocks and gender differences in labor market participation (Afridi et al., 2022; Maitra & Tagat, 2024). Among the few studies that look at floods, the focus has been limited. For example, Canessa and Giannelli (2021) study the impact of flood on women’s paid employment in subsistence activities in Bangladesh but do not consider men’s outcomes. In contrast, my study examines the impact of floods on both men’s and women’s paid labor outcomes beyond subsistence work. Furthermore, I include both the extensive margin (i.e., binary outcome—whether an individual is employed or not) and the intensive margin (i.e., weekly working hours). While Vitellozzi and Giannelli (2024) include both men and women in their analysis, they only focus on unpaid work in family businesses which does not capture the full picture of paid labor markets. This study fills this gap by including all activities under paid labor across self-employment, regular wage work, and informal or casual labor.

Section 2 presents descriptive cross-country evidence on the relationship between flood exposure and gendered labor market outcomes and outlines the conceptual framework explaining the relationship between climate shocks and the gender division of labor. Section 3 provides the case study context for this analysis. Section 4 details the data and research methodology used for empirical analysis. Section 5 presents the results, followed by the conclusion in Section 6.

2 Catastrophic Flood and Gender Gap in Paid Labor: An Overview

The empirical literature provides mixed evidence on how floods reshape gendered labor supply. Some studies find that disasters increase women’s participation in paid work as households attempt to smooth income losses, while others document declines in women’s employment due to

disruptions in labor markets and rising domestic responsibilities. One possible explanation for these seemingly contradictory findings is that the relationship between flood exposure and gendered labor outcomes may be nonlinear. Moderate shocks may induce income-smoothing responses that increase labor supply, whereas severe disasters may disrupt economic activity and intensify unpaid care responsibilities that disproportionately constrain women’s participation in paid work.

To explore this possibility, I present descriptive cross-country evidence on the relationship between flood exposure and gendered labor market outcomes. I combine country-level labor force participation data from the International Labour Organization (ILO) with disaster exposure data from the EM-DAT database. Flood exposure is measured as the percentage of the population affected by floods in a given country-year. To allow time for labor market adjustments following disasters, I use the lagged value of flood exposure. The following specification estimates the relationship between flood exposure and labor outcomes while allowing for nonlinear effects:

$$y_{ct} = \beta_0 + \beta_1 \text{FloodShock}_{ct-1} + \beta_2 \text{FloodShock}_{ct-1}^2 + \mu_c + \gamma_t + \varepsilon_{ct} \quad (1)$$

where y_{ct} denotes the labor market outcome in country c and year t . I consider two outcome variables: (i) the gender gap in labor force participation² and (ii) the female labor force participation rate. FloodShock_{ct-1} represents the percentage of the population affected by floods in the previous year based on EM-DAT records. Country fixed effects (μ_c) control for time-invariant cross-country differences such as geography, institutions, and prevailing gender norms, while year fixed effects (γ_t) capture global shocks affecting labor markets. Including both linear and quadratic terms allows the relationship between flood exposure and labor outcomes to vary with the severity of the disaster.

Figure 1 presents the predicted relationship between lagged flood exposure and gendered labor market outcomes. Two patterns emerge. First, at relatively low levels of flood exposure, female labor force participation increases slightly while the gender gap in labor force participation narrows. This pattern is consistent with a short-run coping response, where households increase labor supply to compensate for income losses following moderate shocks. Second, as flood exposure becomes more severe, the relationship reverses. Female labor force participation declines and the gender gap widens substantially. Large-scale floods can destroy productive assets, disrupt local labor markets, and increase the burden of unpaid domestic and caregiving work within households. In many developing economies, these responsibilities disproportionately fall on women, limiting their ability to engage in paid employment. These findings suggest that moderate flood shocks may temporarily increase women’s labor supply through income-smoothing mechanisms, whereas severe disasters may reinforce existing gender inequalities in access to paid work. This nonlinear relationship can explain the mixed findings in the existing literature.

²It is equal to the difference between male and female labor force participation.

Figure 1: Relationship between Lagged Flood Damage and Predicted Gendered Labor Supply

Conceptual Framework

When a climate event like a flood occurs, it affects human lives through three key pathways: household wealth/assets, natural resources, and health. Floods can lead to significant losses in household wealth and income, particularly for those dependent on climate-sensitive activities such as agriculture and daily wage labor. These economic disruptions create financial strain, often compelling household members to spend more hours in paid labor. At the same time, disruptions in water supply, food availability, and energy access increase domestic work burdens. Climate extremes also exacerbate health risks, particularly for children, the elderly, and individuals with pre-existing conditions. The increased demand for caregiving and domestic chores can reduce the time available for paid labor, while rising healthcare expenses may push household members—regardless of gender—to enter the labor market to cover increased expenditure.

In many developing and less developed countries, social norms dictate that women are primarily responsible for household maintenance and caregiving, while men are expected to seek income outside the home. These norms shape how men and women adjust their labor allocation in response to climate shocks. This is reflected by the factor ‘gender norms’ in Figure 2.

Men, who generally have greater mobility, may migrate to unaffected areas in search of work, while women are more likely to remain in disaster-affected regions and take on increased domestic and caregiving responsibilities (Afridi et al., 2022). Higher dependency burdens tend to reduce women’s time to engage in paid employment.

Figure 2: Conceptual Framework

3 Case Study

Kerala, a southwestern coastal state of India, is bordered by the Arabian Sea on the west and the Western Ghats on the east. The state spans a coastline of 580 km and features three distinct geographical regions: hills and valleys, midlands, and coastal areas. The state's river system consists of 44 rivers, primarily originating in the Western Ghats. Due to its geographical positioning, Kerala is highly vulnerable to multiple natural disasters, including floods, landslides, cyclones, and coastal erosion (World Bank et al., 2018). Approximately 14.8% of the state is flood-prone, and the monsoon season frequently triggers landslides in the hilly regions (World Bank et al., 2018). The map of Kerala is shown in figure A.1, Appendix.

Kerala has 57 large dams, four of which are operated by the Tamil Nadu government. The total live storage capacity of these dams is 5.806 BCM, accounting for 7.4% of the state's annual average runoff of 78 BCM (Central Water Commission, 2018). Seven major reservoirs hold 74% of this capacity (Central Water Commission, 2018). Despite these water management infrastructures, the state remains prone to flooding due to heavy monsoons and inadequate dam management and draining capacities (World Bank et al., 2018).

Kerala received the heaviest downpours between August 8–10, 2018, and August 14–19, 2018. While excessive rainfall is a necessary condition for flooding, the severity of the flood also depends on additional factors such as dam management. In this case, poor reservoir management worsened the flood-induced damage across the state. By early August, most dams were already filled to 90% of their capacity (Kerala State Disaster Management Authority, 2018). Consequently, the heavy downpours led to the opening of 35 dams across the state, including all five gates of the Idukki Dam for the first time in 26 years (Central Water Commission, 2018). The intense rainfall and dam releases led to devastating floods, landslides, and widespread destruction across 13 of Kerala's 14 districts (Central Water Commission, 2018). The floods resulted in 498 confirmed casualties and

displaced over 1.4 million people, who sought refuge in relief camps (World Bank et al., 2018). The floods caused extensive damage to water supply infrastructure, disrupting urban water supply and contaminating drinking water sources. The siltation of intake wells and damage to treatment plants significantly reduced water quality (World Bank et al., 2018). About 83,506 household toilets were damaged, leading to sanitation challenges and potential public health hazards (World Bank et al., 2018).

Figure 3: Pre- and Post-2018 Kerala Floods. The left panel shows Kerala on February 6, 2018, before the floods, while the right panel depicts the region on August 22, 2018, after the floods. Based on false-color imagery, here, bright green indicates vegetation; dark blue represents floodwaters visible in the post-flood image; darker hues in the pre-flood image denote permanent water bodies such as rivers and lakes; white color indicates cloud cover. NASA Earth Observatory images.

The estimated damage was initially valued at INR 19,512 crore (USD 2.8 billion) but was later revised to INR 24,308.35 crore (USD 3.5 billion) as per the Government of Kerala’s memorandum to the Government of India. According to satellite imagery, approximately 65,188 hectares of land were submerged (World Bank et al., 2018).

Table 1: Summary of Infrastructure Damages and Worst-Affected Districts Due to the 2018 Kerala Floods.

Sector	Damage (in USD Million)	Worst impacted Districts
Agriculture (Crops and farmland)	2,159	Idukki, Wayanad, Alappuzha, Pathanamthitta
Livestock	24.6	Ernakulam, Malappuram
Fisheries	20.16	Alappuzha, Thrissur, Kottayam
Small Enterprises & Industry	91.7	Statewide
Tourism	72.7 (Infrastructure) + 243 (Revenue Loss)	Alappuzha, Idukki, Ernakulam

Note: Self-compilation from the joint report on the 2018 Kerala Floods by the Government of Kerala, Asian Development Bank and World Bank (pdna2018).

4 Data and Empirical Strategy

4.1 Data

Information at Individual and Household Level

This paper utilizes data from two rounds of the Periodic Labour Force Survey (PLFS) conducted during four quarters of July 2017–June 2018 and July 2018–June 2019. PLFS is a nationally representative survey conducted by the National Statistical Office (NSO) of India to assess key labor market indicators, including employment, unemployment, and labor force participation. Introduced in July 2017, PLFS is collected on a quarterly basis in each round. These surveys include demographic and socioeconomic information for all household members. My main variable of interest is hours worked for pay by men and women per week. PLFS provides data on hours worked based on activity status—both primary and subsidiary activities for each day of the reference week (Day 1 to Day 7). To obtain a comprehensive measure of paid labor, I aggregate hours worked across both types of activities. Relevant variables at the individual level also include weekly occupation status (broad classification includes total labor force, employment, unemployment, unpaid labor), years of education, highest education level, age, and marital status. At the household level, the surveys collect data on religion, social group, relationships to the household head, and household size. Using the demographic information, I created (i) the sex ratio, which is defined as the number of females per male in a household, and (ii) the dependency ratio, which is defined as the number of dependent family members per working age population in a household.

Despite the richness of the data, there are three notable limitations. First, the PLFS data are available as repeated cross-sections for combined rural and urban areas but panel data for only urban households. Since both rural and urban areas are affected by floods, this analysis focuses on the repeated cross-sectional data. Second, while individuals often divide their time between paid and unpaid work, the PLFS framework classifies individuals engaged in unpaid work as exclusively outside the paid labor force. Thus, the reported daily hours of work only include paid work. Third, PLFS did not start collecting information on migration until July 2020–June 2021.

Information on Climate Shock: Determining Treatment and Control Group

Data on the 2018 Kerala flood damages are obtained from two sources: (a) *Memorandum: Kerala Floods—2018*, prepared by the State Disaster Management Authority, Government of Kerala (Kerala State Disaster Management Authority, 2018); and (b) Google Earth Engine Maps. Because out of 14 districts in Kerala, 13 experienced flood-related damage (Kerala State Disaster Management Authority, 2018), I utilize flood extent estimates derived from Google Earth Engine (GEE). These estimates provide taluk-wise inundation data for Kerala in 2018, based on satellite imagery from

the European Space Agency’s Sentinel-1.³ However, total inundation alone may not fully capture flood exposure because areas with larger inundated areas may simply have a greater total land area. To better account for inhabited regions, I incorporate the total area and population of each subdivision from the 2011 Census to estimate the affected population in each district:

$$Exposure_d = \sum_{i=0}^d \left(\frac{Inundation_i}{Total\ Area_i} \times Population_i \right) \quad (2)$$

This measure accounts for human exposure to flooding rather than just the physical extent of inundation. It is evident from Table A.1 that Kozhikode, Malappuram, Palakkad, Thrissur, Kottayam and Alappuzha are highly exposed to floods and the remaining districts are relatively less exposed to floods. This is shown in Figure 4. For the main results, I use highly flood-exposed districts as the treatment group. Since lesser affected districts may have had little prior exposure, flood impact could be substantial in less affected districts. Hence, I include all districts of the neighboring state, Tamil Nadu, as control. In early December 2017, however, a cyclone named ‘Ockhi’ passed by Kerala and Tamil Nadu while heading towards Lakshadweep. This cyclonic storm heavily impacted two districts (out of 14) in Kerala—Ernakulam and Thiruvananthapuram—and four districts (out of 32) in Tamil Nadu—Kanyakumari, Thoothukudi, Tirunelveli and Ramanathapuram. To ensure a cleaner comparison, I exclude these districts.

Table 2 presents summary statistics for key continuous and binary variables for treatment and control groups. Men’s employment participation is high across both groups—58.4% in the treatment group and 61.7% in the control group. In contrast, women’s participation is much lower, at 15.6% in the treatment group and 24.8% in the control group—which reflects the well-documented gender disparities in the Indian labor market (National Statistical Office, 2021). In terms of the intensive margin, men in the treatment group report an average of 25.02 hours of weekly work while those in the control group work 30.31 hours per week. Among women, the average is 11.24 hours of weekly work in the control group while in the treatment group it is 6.41 hours of weekly work. Demographic characteristics are similar across the treatment and control groups. The average age of men and women is around 32–33 years and mean years of education vary approximately between 7–8 years, that is, completion of secondary education. On average, overall household size is 4 in the control group and nearly 5 in the treatment group. Households in the treatment group also report a higher average number of dependent members (1.5 vs. 1.11) and also a higher sex ratio.

³Unlike conventional optical satellites, Sentinel-1 uses radar-based imaging and enables flood detection under all weather conditions both during day and night. This particularly makes it reliable to assess flood extent in regions affected by monsoon cloud cover.

Figure 4: Kerala districts by flood exposure. Dark blue colored regions represent districts which are highly exposed to flood. Light blue colored regions denote districts which are less exposed to flood. Hatched districts are excluded from analysis.

Table 2: Summary Statistics for Binary and Continuous Variables.

Variable	Treatment			Control		
	No. of Obs.	Mean	SD	No. of Obs.	Mean	SD
<i>Individual Level</i>						
Employment participation (men)	11,848	0.584	0.493	28,432	0.617	0.486
Employment participation (women)	13,302	0.156	0.363	28,824	0.248	0.432
Weekly working hours (men)	10,958	25.020	26.110	26,562	30.310	27.780
Weekly working hours (women)	12,386	6.410	16.269	27,093	11.240	20.380
Age of men (years)	11,848	31.980	19.696	28,432	31.286	18.190
Age of women (years)	13,302	33.196	19.275	28,824	31.996	17.905
Years of formal education (men)	11,848	8.209	4.641	28,432	8.126	5.135
Years of formal education (women)	13,302	8.313	4.865	28,824	7.212	5.395
<i>Household Level</i>						
Overall household size	26,877	4.632	1.943	59,908	4.140	1.557
No. of working age members	26,877	2.831	2.216	59,908	2.796	2.114
No. of dependent members	26,877	1.495	1.746	59,908	1.108	1.434
Sex ratio	19,375	1.042	0.930	45,154	0.937	0.842

Notes: This table reports summary statistics for continuous variables used in analysis. It shows the stark gender differences in paid labor supply within treatment and comparison districts.

4.2 Empirical Strategy

To estimate the effects of the 2018 August flood, I use a difference-in-differences (DID) strategy, separately for men and women:

$$y_{ihdt}^s = \beta_0^s + \beta_1^s Treat_{ihd} + \beta_2^s Post_t + \beta_3^s (Treat_{ihd} \times Post_t) + \beta_4^s X'_{ihdt} + \beta_5^s Z'_{hdt} + \tau_d^s + \varepsilon_{ihdt}^s \quad (3)$$

where y_{ihdt}^s represents the paid labor outcome for individual i from household h in district d at quarter t . This paid labor outcome is measured in two ways: (a) extensive margin: a binary variable which takes value 1 if individual i from household h in district d at quarter t participates in the paid labor force and 0 otherwise; (b) intensive margin: a continuous variable that captures hours spent on paid labor by individual i from household h in district d at quarter t .

$Treat_d$ is a treatment dummy that takes value 1 if individual i from household h is located in an affected district and 0 otherwise. $Post_t$ is a time dummy which takes value 1 for all quarters after the flood has occurred and 0 before the flood. X'_{ihdt} is the vector of individual level characteristics which include age, education, and marital status. Z'_{hdt} is the vector of household level characteristics which include religion, social group, household size, and monthly consumption spending. τ_d^s is a district fixed effect that controls for unobserved district-level factors which may impact the outcome variable. ε_{ihdt}^s is the error term, which is clustered at the household level. Equation (3) is estimated separately for $s \in \{female, male\}$.

Figure 5: Timeline of Flood and Data Availability

5 Results

5.1 Parallel Trend Test: Event Study Results

To validate the difference-in-differences identification strategy, it is important to test the presence of pre-event trends between treatment and control groups. If there exist no statistically significant differences in pre-event trends, it supports the validity of attributing the post-event differences in outcomes to the 2018 August flood and we can infer the regression estimates as causal results.

I assess this assumption using an event study analysis where I present the effect of the 2018 August flood on paid labor outcomes for each quarter during July 2017–June 2019 with the base period as April 2018–June 2018 ($t = -1$). The estimations from this event study analysis are given in Panels (A)–(D) of Figure 6. Panels (A)–(B) report the effects on the extensive margin (employment participation) while Panels (C)–(D) report results for the intensive margin (weekly working hours).

For employment participation (Panels (A)–(B), Figure 6), there are no statistically significant differences in paid labor trends for men (Panel (A)) prior to the flood. However, I cannot rule out the possibility of pre-flood differences in employment participation trends for women (Panel (B)). In the case of weekly working hours (Panels (C)–(D)), there are no statistically significant differences in trends for both men and women before the 2018 August flood. After the flood, both employment participation and weekly working hours decline significantly for both men and women (Panels (A)–(D)). However, the timing and extent of these effects differ by gender. For men, the reduction in paid labor outcomes occurs in the same quarter as the flood event but it eventually recovers (Panels (A) and (C)). In contrast, for women, the negative effect emerges with a lag of one quarter following the flood (Panels (B) and (D)). This suggests that while men experience immediate labor market disruptions, women’s paid labor outcomes are affected more gradually in the aftermath of the flood. This gradual effect for women likely reflects increased domestic and caregiving responsibilities after the disaster (Akter, 2021). Moreover, women in Kerala are concentrated in service (formal and

informal) sectors (Alexander, 2025), which require stable conditions, restoration of public services and reopening of workplaces, and hence recovery takes time.

Figure 6: Event Study Results for Paid Labor Outcomes in highly exposed districts as treatment group. Here, the quarter April 2018– June 2018 ($t = -1$) is used as reference period. Note: Circular dots and vertical lines show estimates and 95% confidence intervals.

5.2 Main Regression Results

I report the estimated effect of the 2018 August flood on labor market outcomes using Equation (3) in Table 3. Columns (1)–(2) report the results without controls, while Columns (3)–(4) include individual-level and household-level controls. Panel A shows the estimates on the extensive margin (employment participation), while Panel B presents the estimates on the intensive margin (hours worked per week). In each panel, the first row reports the coefficient on the interaction term ($Treat_d \times Post_t$) while the second and third rows report the effects of $Post_t$ and $Treat_d$, respectively. The mean of the dependent variable for the control group is reported at the bottom of each panel.

Panel A shows that the 2018 floods had no statistically significant impact on employment participation for either women or men. Women’s employment participation declined by 1.5 percentage points (pp) (Column (1), Panel A) and men’s participation increased by 2.6 pp (Column (2), Panel A) in treated areas after the flood, but neither effect is statistically significant. These findings remain consistent after controlling for individual- and household-level characteristics: women’s participation fell by 1.6 pp and men’s employment participation rose by 1.7 pp (Columns (3)–(4), Panel A). The small positive effect on men’s employment participation may reflect marginal entry into the labor force as households sought to cope with income losses after the flood (e.g., Afridi et al., 2022; Musungu et al., 2024).

Panel B presents results for the intensive margin of labor market outcomes. After controlling for individual and household level characteristics, hours worked per week fell significantly for both women and men following the floods. Specifically, women reduced their weekly paid labor by 1.42

hours (Column (3), Panel B). Compared to the mean working hours of 6.38 hours per week of the control group, this reduction corresponds to a decline in labor hours by nearly 23.5%. For men, the results show a reduction of 1.40 hours per week (Column (4), Panel B). Relative to the mean of 26.06 working hours per week of the control group, the estimated decrease for men represents about a 7.3% fall in hours worked per week.

Thus, the results suggest that the adverse effects of the 2018 floods on paid labor outcomes were primarily concentrated along the intensive margin rather than the extensive margin. While individuals did not significantly enter or exit employment following the floods, those who remained employed substantially reduced their labor supply, as measured by hours worked per week. This is consistent with the literature on negative effects of disasters on local labor markets (e.g., Gröger & Zylberberg, 2016; Skoufias et al., 2011). The proportionate decline in hours worked was larger for women, which indicates that female workers may have been more vulnerable to disruptions in labor market engagement following extreme climate events. One possible explanation is that women often bear a disproportionate burden of increased household and caregiving responsibilities in the aftermath of environmental disasters, which can limit their ability to sustain pre-flood levels of paid work (Afridi et al., 2022). Moreover, substantial disruptions in local infrastructure—including damage to roads, bridges, and public transport—likely restrict access to workplaces and hence working hours for both men and women.

Labor Market Outcomes in Less Affected Districts. While the previous section focused on districts that were severely affected by the 2018 August flood, it is equally important to examine labor market responses in relatively less exposed areas. These areas are often overlooked in disaster recovery efforts since they are presumed to be relatively more resilient. However, many of such areas were affected for the first time, which could disrupt local labor markets despite lower levels of destruction. To explore this, I re-estimate Equation (3) using less affected districts by the 2018 August flood in Kerala—Kasargod, Kannur, Wayanad, Palakkad, Idukki, Pathanamthitta and Kollam—as the treatment group. These are represented by white colored areas in Figure 4. The control group continues to be the same. Accounting for both household and individual level controls, the flood reduced women’s employment participation by 0.1 pp, though not statistically significant (Column (3), Panel A, Table A.2). However, men experienced an increase in employment participation by 3.2 pp after the flood (Column (4), Panel A, Table A.2). This suggests that men may have been more successful with post-flood recovery in less-affected districts compared to those in more affected districts. It could possibly be due to higher employment in recovery-related jobs such as reconstruction of damaged buildings.

Table 3: Regression results for paid labor outcomes in highly exposed districts

Individual level controls	✗	✗	✓	✓
Household level controls	✗	✗	✓	✓
District fixed effects	✓	✓	✓	✓

Note: In this table, treatment group consists of all districts in Kerala with high exposure to flood; control group consists of all districts in Tamil Nadu. Standard errors clustered at the household level are reported in parentheses. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$.

In the case of the intensive margin, I observe a decline in women's paid labor hours even in less affected districts. After the flood, women reduced their paid labor by 1.55 hours per week, which is consistent with my main findings. This underscores the vulnerability of female labor supply to environmental shocks even at moderate levels. Men also experienced a reduction in their paid labor hours but it is marginal and statistically insignificant. Though the magnitude of men's paid labor hours is much lower in less affected districts compared to those in highly affected districts as in the previous section, the direction of the effect remains similar to the main regression results.

5.3 Robustness Check

To test the robustness of the main findings, I estimate Equation (3) using alternative treatment definitions while the control group remains unchanged. These alternative specifications help assess whether the observed labor market effects of the 2018 flood were concentrated in the most affected

areas or present across other aspects of flood exposure. Across all robustness checks, similar results are found: while employment participation of men does not seem to be impacted by the flood, their working hours declined significantly after the flood. In the case of women, both their participation and working hours reduced after the flood.

5.3.1 Districts Most Affected by Flood-Induced Landslides

Here, I restrict the treatment group to districts in Kerala that experienced the most severe flood-induced landslides—a secondary disaster linked to floods. Wayanad and Idukki accounted for 42% of all landslides during the 2018 August floods. Wayanad experienced heavy rainfall which triggered soil slippage and landslides (Kerala State Disaster Management Authority, 2018; Rajeev Gandhi Institute for Development Studies, 2018). Pathanamthitta experienced massive landslides in hilly areas such as Chittar, Seethathode and Sabarimala (Kerala State Disaster Management Authority, 2018; Rajeev Gandhi Institute for Development Studies, 2018). Thus, the treated districts include Wayanad, Kozhikode, Idukki, Kottayam and Pathanamthitta. This is shown in Figure A.2. The results are shown in Table 4, which remain consistent with the main findings.

After the flood, Panel A shows that women’s employment participation fell by 3.3 pp (Column (3), Panel A) while men experienced an insignificant increase (Columns (2) and (4), Panel A). This suggests that men may have had post-flood recovery while women did not. In the case of the intensive margin, I find that the flood reduced women’s paid labor hours by nearly 2.5 hours per week (Columns (1) and (3), Panel B). Men also experienced a decline in their paid labor by 1.8 hours per week (Column (4), Panel B). These results show that flood-induced landslides further worsen paid labor outcomes whereby women are disproportionately worse off.

5.3.2 Districts Closest to Mismanaged Dams

Here, I define the treatment group as districts closest to dams which were most mismanaged during the 2018 flood. Particularly, Idukki district—home to the large Idukki dam and Cheruthoni dam—saw poor reservoir management such as use of flood cushion capacity and delayed water releases (Kerala State Disaster Management Authority, 2018). Similarly, dam discharges from Idamalayar, Mullaperiyar, Upper Sholayar, Peringalkuthu and Bhoothathankettu contributed to flooding in the districts of Kottayam, Pathanamthitta and Thrissur (Rajeev Gandhi Institute for Development Studies, 2018). Thus, the treated districts include Palakkad, Thrissur, Idukki, Kottayam and Pathanamthitta. This is shown in Figure A.3. Poor governance and operational decisions of dams are likely to amplify flood damage (Kerala State Disaster Management Authority, 2018). The results are shown in Table 5, which align with the main findings.

Table 4: Regression Results: Exposure to flood-induced landslides

$Post_t$	-0.479 (0.987)	0.666 (1.287)	-0.304 (0.971)	0.359 (1.113)
$Treat_d$	-4.411** (1.897)	-12.502*** (2.529)	-2.700 (2.007)	-11.489*** (2.346)
Control group mean	7.88	27.91	7.88	27.91
No. of observations	26,903	26,490	26,903	26,490
R-squared	0.027	0.024	0.092	0.383
Individual level controls	✗	✗	✓	✓
Household level controls	✗	✗	✓	✓
District fixed effects	✓	✓	✓	✓

Note: In this table, treatment group consists of all districts in Kerala affected by flood-induced landslides; control group consists of all districts in Tamil Nadu. Standard errors clustered at the household level are reported in parentheses (*** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$).

After the flood, Panel A shows that women's employment participation fell by 1.8 pp (Column (3), Panel A) while men experienced an increase by 3.2 pp (Column (4), Panel A). This shows that men are likely to have post-flood recovery while women did not. Panel B shows the results for the intensive margin. Here, I find that the flood reduced women's paid labor hours by nearly 1.55 hours per week (Column (3), Panel B). Men also experienced a decline in their paid labor by 0.3 hours per week after accounting for controls (Column (4), Panel B). These estimates suggest that proximity to mismanaged dams worsened the negative effects of floods on paid labor, which is especially skewed against women.

5.4 Heterogeneous Effects

5.4.1 Location of Dwelling (Rural/Urban)

Rural and urban labor markets differ in terms of composition and access to opportunities. In India, rural areas are predominantly agricultural and heavily reliant on informal and casual labor. As a result, individuals and households dwelling in rural areas are especially vulnerable to climate shocks like floods which can destroy crops, livestock, and local enterprises. In contrast, urban areas offer more diversified employment in manufacturing, construction and service sectors. Moreover, gender norms and expectations regarding paid labor participation also vary across rural and urban areas: rural women typically face more mobility and employment restrictions than their urban counterparts.

I explore whether the 2018 Kerala floods had differential effects on paid labor market outcomes across rural and urban areas by estimating Equation (3) separately by location of dwelling. In Table 6, Panel A presents results for employment participation (extensive margin), while Panel B shows results for hours worked per week (intensive margin). In the case of the extensive margin, rural women experienced a reduction of 3.2 pp in employment participation (Column (1), Panel A) while urban women witnessed a smaller decline of 0.7 pp after the flood (Column (3), Panel A). Rural men faced a decline in employment by 0.9 pp (Column (2), Panel A), whereas urban men show a positive though insignificant increase of 1.5 pp (Column (4), Panel A). This reflects that urban men experienced a relatively faster employment recovery compared to rural men due to more diversified access to non-agricultural employment. In terms of the intensive margin, the flood had a statistically significant effect on rural labor hours for both men and women.

Rural women faced a statistically significant reduction in paid labor by 1.63 hours per week after the flood, which is about 13.9% decline relative to the average workload of the control group (Column (1), Panel B). Rural men also experienced a decline of 2.94 working hours per week, which is a 10.7% drop from their control group’s average paid labor hours (Column (2), Panel B). The effects were negligible and statistically insignificant for both urban men and women (Columns (3)–(4), Panel B). Thus, the flood had a more adverse impact on rural labor markets, particularly on women’s paid labor.

5.4.2 Employment by Sector

The type of employment—whether self-employed, regular wage work or casual labor—shapes the extent to which individuals experience and respond to shocks including climate events.⁴ Casual labor, which includes informal and daily-wage based work, is particularly sensitive to economic shocks. Regular wage work tends to offer relatively more stability while self-employment depends heavily on personal assets and local resources which are likely to be compromised by disasters. After a flood, people are likely to lose jobs and may shift to self-employment as an alternative means to support themselves. To explore how the 2018 Kerala floods affect paid labor outcomes by different sectors of employment, I estimate Equation (3) separately for self-employment, regular wage labor and casual labor. Table 7 shows these results, where Panel A and Panel B show the estimates for employment participation (extensive margin) and weekly working hours (intensive margin).

⁴There were many missing values in terms of individuals’ detailed occupations—primarily agriculture, manufacturing and service sectors.

Individual level controls	✓	✓	✓	✓
Household level controls	✓	✓	✓	✓
District fixed effects	✓	✓	✓	✓

Note: In this table, I report heterogeneous effects of flood exposure on gendered labor supply separately for rural and urban sectors. Standard errors clustered at the household level are reported in parentheses.

*** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$.

On the extensive margin, the flood did not have a statistically significant effect on women's employment participation in any sector. However, the estimates suggest some modest sectoral shifts: participation in self-employment increased by 0.5 pp (Column (1), Panel A), while participation in regular and casual labor reduced by 1.1 pp (Column (3), Panel A) and 2.2 pp respectively (Column (5), Panel A). For men, the flood led to a statistically significant increase of 1.5 pp in self-employment participation (Column (2), Panel A). This may reflect a shift toward more home-based work after the flood. After the flood, however, participation in regular and casual labor declined by 1.2 pp and 2.6 pp respectively, though not statistically significant (Columns (4) and (6), Panel A).

Similar trends are observed in the case of the intensive margin. After the flood, women experienced a reduction in regular wage labor by 1.42 hours per week (Column (3), Panel B) and an even larger

drop in casual labor by 2.26 hours per week (Column (5), Panel B). In the case of self-employment, however, the change in women’s weekly working hours remained minimal and statistically insignificant (Column (1), Panel B). On the contrary, men faced a significant drop in the case of casual labor by 3.09 hours per week (Column (6), Panel B). Hours worked in self-employment also declined by 1.89 hours per week (Column (2), Panel B). The effect is negligible for regular wage work in the case of men (Column (4), Panel B).

These results highlight two key insights. First, casual labor appears to be most vulnerable to floods. The reduction in casual labor hours for both men and women highlights how fragile daily-wage work is to external shocks like floods. Second, self-employment may serve as a fallback option for men as reflected in their increased participation. But this did not translate into a rise in their hours worked, which suggests reduced business activity—possibly due to flood-related damage to capital, decline in demand for output or destruction of supply chains. Thus, while self-employment may be a coping mechanism for men, it does not fully insure them against income loss after the flood.

Note: In this table, I report heterogeneous effects of flood exposure on gendered labor supply separately by types of employment. Standard errors clustered at the household level are reported in parentheses. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$.

5.4.3 Gender Norms

Gender norms assign primary responsibility for home production and caregiving to women. This, in turn, influences women’s participation in paid labor, especially during environmental crises. Such effects can vary by marital status and household dependency burden. Married women often face greater time constraints due to expectations around domestic responsibilities and caregiving for children or the elderly. Similarly, working-age individuals in households with a higher share of dependents are more likely to engage in unpaid domestic and care work compared to those in low-dependency households. Because gender norms expect women to shoulder these responsibilities, the effect of exogenous shocks such as floods disproportionately worsens women’s paid labor compared to men.

To explore this, Tables 8 and 9 examine the heterogeneity in the paid labor responses to the 2018 Kerala flood by marital status and dependency burden respectively. In each of these tables, Panel A shows the results for the extensive margin, that is, employment participation, and Panel B presents the estimates for the intensive margin, that is, weekly working hours, separately for men and women.

(a) Marital status. In the case of the extensive margin, unmarried women faced a statistically significant increase in employment participation by 3.6 pp (Column (1), Panel A, Table 8), whereas unmarried men experienced a negligible and insignificant change in employment (Column (2), Panel A). In contrast, married women experienced a decline of 3.3 pp in employment participation (Column (3), Panel A), while married men saw an increase of 2.7 pp (Column (4), Panel A). The effect of the 2018 Kerala flood revealed sharper gender differences in the case of the intensive margin (hours worked per week). Among unmarried individuals, women increased their paid labor by 1.86 hours per week (Column (1), Panel B), while men saw a negligible change in paid labor hours per week (Column (2), Panel B). Married women, on the contrary, experienced a statistically significant drop of 1.93 hours per week, but married men faced a relatively smaller and insignificant decline of 1.37 hours per week (Columns (3)–(4), Panel B).

These results suggest a contrasting pattern in paid labor outcomes among men and women based on their marital status⁵. Unmarried women may have more flexibility to respond to paid labor market opportunities after the flood mainly due to fewer domestic responsibilities. Married women, on the contrary, face substantial time constraints because of social expectations around domestic work and caregiving. Moreover, time spent on domestic chores like collecting water and cooking increases and similarly more time is required for caregiving responsibilities in response to flood shocks. As a result, married women are more likely to reduce their paid labor outcomes.

⁵Note that I only show the case of unmarried and married people. I did not show the case of widowed/divorced because the sample size for widowed/divorced men is very small (less than 600).

Table 8: Heterogeneous effects by marital status

Note: In this table, I compare the heterogeneous effects of flood exposure on gendered labor supply separately among unmarried and married individuals. Standard errors clustered at the household level are reported in parentheses. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$.

(b) Dependency burden. High dependency is defined based on the number of children (less than 11 years) and elderly (above 70 years) in a household compared to working family members. If a household has more than 50% dependent family members, it is a highly dependent household. On the other hand, if a household has less than or equal to 50% dependent family members, it is characterized by low dependency. In both Panels A and B of Table 9, Columns (1)–(2) show results for paid labor outcomes of women and men in households characterized by high dependency while Columns (3)–(4) present estimates for paid labor outcomes of women and men in households characterized by low dependency.

In high dependency households, women experienced a decline in employment participation by 2.5 pp (Column (1), Panel A) while men faced an increase in employment participation by 3.0 pp (Column (2), Panel A). On the contrary, in low dependency households, men witnessed a drop in employment

participation by 0.4 pp (Column (4), Panel A) while women saw a decline in their employment by 0.6 pp after the flood (Column (3), Panel A). Though the results are not statistically significant, these indicate that men may be more responsive to paid labor under dependency pressure, while women's paid labor participation is further deterred due to caregiving responsibilities. Panel B also shows similar results for the intensive margin. In high dependency households, women reduced their paid labor by 1.5 hours per week (Column (1), Panel B) while men faced an insignificant drop in their paid labor hours (Column (2), Panel B). In low-dependency households, women experienced a decline in their paid labor hours by nearly 1.1 hours per week (Column (3), Panel B), which is less than the 1.9-hour decline for men (Column (4), Panel B).

Note: In this table, I compare the heterogeneous effects of flood exposure on gendered labor supply separately by dependency burden. Using median dependency ratio, I classify households into high versus low dependency. Standard errors clustered at the household level are reported in parentheses. *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$. Standard errors clustered at the household level are reported in parentheses (*** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$).

6 Conclusion

Floods can affect livelihoods both directly by damaging physical infrastructure and assets and indirectly by (a) disrupting markets and mobility, and (b) exacerbating domestic and care work. In less developed countries like India, traditional gender norms shape participation in paid work and hence environmental disasters like flash floods can have unequal consequences for men and women. This paper examines the gendered labor market effects of the 2018 Kerala floods, which is one of the most catastrophic flood events in recent Indian history. I find that both men and women faced a decline in their paid labor hours per week after the flood, but the effect is more pronounced among women.

I also show that the extent to which floods impact the gendered paid labor market varies by location of dwelling, sector of employment, marital status and dependency burden. Both men and women are worse off if they are dwelling in rural areas. Labor markets are more resilient for both men and women in urban areas. Casual laborers are most vulnerable to flood shocks. Besides, men are found to be shifting towards self-employment work after the flood, though their increased participation is not automatically translated into more working hours. This is plausible because lack of jobs may induce primary earners to become self-employed but inadequate infrastructure, assets and capital might not allow them to work enough. Moreover, the findings suggest that women's work is more vulnerable to their marital status and greater burden of unpaid care work. Married women were less likely to work after the flood unlike their unmarried counterparts. Similarly, women coming from households with a higher share of children and elderly faced a reduction in their paid labor compared to those from low-dependency households.

As extreme weather events become more frequent and severe, policymakers must adopt gender-sensitive approaches in disaster response and economic recovery strategies. Faster restoration of infrastructure and stable conditions is important to combat loss in production of service sector activities. Safe transport, emergency childcare support and government employment programs can deter from reinforcing social norms and gender inequality in labor market. Targeted financial support to restore and repair physical capital in primary sector can address men's reduction in working hours. Future work could examine how flood intensity impact job matching and how the pace of post-flood transport reopening affect gender inequality in labor market. These are important because liquidity and mobility constraints can lead to poor job match and reinforce gender disparities.

Table A.1: Population Weighted Exposure to the 2018 Flood by Districts in Kerala.

District	District Code	Weighted Exposure
Thiruvananthapuram	14	7,061.041
Kollam	13	5,193.163
Pathanamthitta	12	5,966.461
Alappuzha	11	30,114.469
Kottayam	10	31,980.332
Idukki	9	1,266.632
Ernakulam	8	10,152.947
Thrissur	7	29,619.247
Palakkad	6	7,181.992
Malappuram	5	11,167.332
Kozhikode	4	12,309.486
Wayanad	3	3,615.535
Kannur	2	3,451.860
Kasaragod	1	711.299

Note: Red-shaded rows indicate districts with high exposure to the flood. Grey-shaded rows refer to those districts which were dropped from the analysis.

Table A.2: Regression results for paid labor outcomes by gender in less exposed districts
